## Abstract

We generalize the standard vehicle routing problem with time windows by allowing both traveling times and traveling costs to be time-dependent functions. In our algorithm, we use a local search to determine routes of the vehicles. When we evaluate a neighborhood solution, we must compute an optimal time schedule for each route. We show that this subproblem can be efficiently solved by dynamic programming, which is incorporated in the local search algorithm. The neighborhood of our local search consists of slight modifications of the standard neighborhoods called 2-opt\*, cross exchange and Or-opt. We propose an algorithm that evaluates solutions in these neighborhoods more efficiently than the ones computing the dynamic programming from scratch by utilizing the information from the past dynamic programming recursion used to evaluate the current solution. We further propose a filtering method that restricts the search space in the neighborhoods to avoid many solutions having no prospect of improvement. We then develop an iterated local search algorithm that incorporates all the above ingredients. Finally we report computational results of our iterated local search algorithm compared against existing methods, and confirm the effectiveness of the restriction of the neighborhoods and the benefits of the proposed generalization.

## 1. Introduction

The *vehicle routing problem* (VRP) is the problem of minimizing the total travel distance of a number of vehicles, under various constraints, where every customer must be visited exactly once by a vehicle [1–3]. This is one of the representative combinatorial optimization problems and is known to be NP-hard. The traveling salesman problem (TSP) can be viewed as a special case of VRP in which the number of vehicles is one. TSP has been intensively studied for many decades [4] and VRP is under intensive study as well. Among variants of VRP, the VRP with capacity and time window constraints, called the *vehicle routing problem with time windows* (VRPTW), has been widely studied

in the last decade [5–8]. The capacity constraint signifies that the total load on a route cannot exceed the capacity of the assigned vehicle. The time window constraint signifies that each vehicle must start the service at each customer in the period specified by the customer. The VRPTW has a wide range of applications such as bank deliveries, postal deliveries, school bus routing and so on, and has been a subject of intensive research focused mainly on heuristic and metaheuristic approaches. See extensive surveys by Bräysy and Gendreau [9,10] for heuristic and metaheuristic approaches.

A constraint is called *hard* if it must be satisfied, while it is called *soft* if it can be violated. The violation of soft constraints is usually penalized and added to the objective function. The VRP with hard (resp., soft) time window constraints is abbreviated as VRPHTW (resp., VRPSTW). For VRPHTW, even just finding a feasible schedule with a given number of vehicles is known to be NP-complete in the strong sense, because it includes the (one-dimensional) bin packing problem as a special case [11]. Hence it may not be reasonable to restrict the search only within the feasible region of VRPHTW, especially when the constraints are tight. Moreover, in real-world situation, time window and capacity constraints can be often violated to some extent. Considering these, the two constraints (i.e., time window constraint and capacity constraint) are treated as soft in this paper. To evaluate constraint violation, we use cost functions, which can be nonconvex and/or discontinuous as long as they are piecewise linear. This formulation is quite general; e.g., one or more time slots can be assigned to each customer.

In real situations, traveling times are often dependent on the departure times and they cannot be treated as constants in such cases (e.g., rush-hour traffic jam). For TSP, the generalization with time-dependent traveling times is called the *time-dependent traveling salesman problem* (TDTSP) and is well-studied [12–14]. On the contrary, to the best of our knowledge, not much has been investigated on similar generalizations of VRPTW except for a few papers. Ichoua et al. [15] considered a formulation in which each customer has only one time window. Desaulniers et al. [16] presented a branch-and-bound framework for a very general model that can handle time-dependency and various other issues. In this paper, we introduce traveling time and cost functions between each customer, whose values are dependent on the start time of traveling. These functions can be nonconvex and/or discontinuous as long as they are piecewise linear. Although we assume some property for each traveling time function, any functions satisfying the FIFO condition considered in [15] can still be represented, and the problem is fairly general. Our model generalizes that of Ichoua et al. in that it can allow more flexible time penalty function for each customer, and that of Ibaraki et al. [17] in that it can treat time-dependent traveling time and cost.

In our algorithm, we use local search to determine the routes of vehicles. When we evaluate a neighborhood solution, we need to solve the problem of determining the optimal start times on each route. In Ichoua et al., they solve this subproblem approximately (for their restricted formulation), but solve it exactly only for the best  $M$ -approximate neighborhood solutions ( $M$  is a parameter). We show that this subproblem can be efficiently solved with dynamic programming. The time complexity of our dynamic programming algorithm is the same as that of Ibaraki et al. [17] in spite of its generality if each traveling time and cost is a constant. This dynamic programming is incorporated in the local search algorithm. In our local search, we use the standard neighborhoods called 2-opt\*, cross exchange and Or-opt with slight modifications. We can evaluate the solutions in these neighborhoods efficiently by utilizing the information from the past dynamic programming recursion. We further propose a filtering method to restrict the search in the neighborhoods to avoid many solutions having no prospect of improvement. For the 2-opt\* neighborhood, even with this restriction, we will not miss a better solution in the neighborhood if there is any. We develop an iterated local search algorithm incorporating all the above ingredients. Finally we report computational results on benchmark instances, and confirm the effectiveness of the restriction of the neighborhood. We compare the performance of our iterated local search algorithm against existing methods, and discuss the benefits of the proposed generalization.

## 2. Problem

Here we formulate the time-dependent vehicle routing problem with time windows. Let  $G = (V, E)$  be a complete directed graph with vertex set  $V = \{0, 1, \dots, n\}$  and edge set  $E = \{(i, j) \mid i, j \in V, i \neq j\}$ , and  $M = \{1, 2, \dots, m\}$  be a vehicle set. In this graph, vertex 0 is the depot and other vertices are customers. Each customer  $i$ , each vehicle  $k$  and each edge  $(i, j) \in E$  are associated with:

- (i) a fixed quantity  $a_i$  ( $\geq 0$ ) of goods to be delivered to  $i$ ,
- (ii) a time window cost function  $p_i(t)$  of the start time  $t$  of the service at  $i$  ( $p_0(t)$  is the time window cost function of the arrival time  $t$  at the depot),

Fig. 1. An example of  $\lambda_{ij}$  which satisfies condition (1), and a function  $\bar{\lambda}$  which does not satisfy condition (1).

- (iii) a capacity  $u_k$  ( $\geq 0$ ) of  $k$ ,
- (iv) a traveling time function  $\lambda_{ij}(t)$  and a traveling cost function  $q_{ij}(t)$  from  $i$  to  $j$  when the start time is  $t$ .

We assume  $a_0 = 0$  without loss of generality. Each time window cost function  $p_i(t)$  is nonnegative, piecewise linear and lower semicontinuous (i.e.,  $p_i(t) \leq \lim_{\varepsilon \rightarrow 0} \min\{p_i(t + \varepsilon), p_i(t - \varepsilon)\}$  at every discontinuous point  $t$ ). Note that  $p_i(t)$  can be nonconvex and discontinuous as long as it satisfies the above conditions. We also assume  $p_i(t) = +\infty$  for  $t < 0$  so that the start time  $t$  of the service is nonnegative. We assume that each traveling cost function  $q_{ij}(t)$  satisfies the same conditions as  $p_i(t)$  (i.e., nonnegative, piecewise linear, lower semicontinuous and  $q_{ij}(t) = +\infty$  for  $t < 0$ ). We assume that each traveling time function  $\lambda_{ij}(t)$  is nonnegative, piecewise linear and lower semicontinuous. The number of linear pieces of these functions are assumed to be finite. These assumptions ensure the existence of an optimal solution. We further assume that  $\lambda_{ij}(t)$  satisfies

$$t + \lambda_{ij}(t) = t' + \lambda_{ij}(t') \Rightarrow t + \lambda_{ij}(t) = \alpha t + (1 - \alpha)t' + \lambda_{ij}(\alpha t + (1 - \alpha)t'), \quad 0 \leq \alpha \leq 1 \quad (1)$$

unless otherwise stated (see an example in Fig. 1). In Fig. 1,  $s = t + \lambda_{ij}(t)$  is the arriving time at  $j$  when a vehicle departs from  $i$  at  $t$ . It is known that the FIFO condition in [15] (i.e.,  $t \leq t' \Rightarrow t + \lambda_{ij}(t) \leq t' + \lambda_{ij}(t')$ ) implies condition (1). In our problem, the linear pieces of each piecewise linear function are given explicitly (i.e., the number of linear pieces is a part of the input size).

Let  $\sigma_k$  denote the route traveled by vehicle  $k$ , where  $\sigma_k(h)$  denotes the  $h$ th customer in  $\sigma_k$ , and let

$$\sigma = (\sigma_1, \sigma_2, \dots, \sigma_m).$$

Note that each customer  $i$  is included in exactly one route  $\sigma_k$ , and is visited by vehicle  $k$  exactly once. We denote by  $n_k$  the number of customers in  $\sigma_k$ . For convenience, we define  $\sigma_k(0) = 0$  and  $\sigma_k(n_k + 1) = 0$  for all  $k$  (i.e., each vehicle  $k \in M$  departs from the depot and comes back to the depot). Moreover, let  $s_i$  be the start time of service at customer  $i$  (by exactly one of the vehicles) and  $s_k^a$  be the arrival time of vehicle  $k$  at the depot, and let

$$s = (s_1, s_2, \dots, s_n, s_1^a, s_2^a, \dots, s_m^a).$$

We assume  $s_0 = 0$  for convenience of explanation. Let  $t_i$  be the departure time of a vehicle from customer  $i$  and  $t_k^l$  be the departure time of vehicle  $k$  from the depot, and let

$$t = (t_1, t_2, \dots, t_n, t_1^l, t_2^l, \dots, t_m^l).$$

Note that each vehicle is allowed to wait at customers before starting services and before traveling.

Let us introduce 0–1 variables  $y_{ik}(\sigma) \in \{0, 1\}$  for  $i \in V \setminus \{0\}$  and  $k \in M$  by

$$y_{ik}(\sigma) = 1 \iff i = \sigma_k(h) \text{ holds for exactly one } h \in \{1, 2, \dots, n_k\}.$$

That is,  $y_{ik}(\sigma) = 1$  if and only if vehicle  $k$  visits customer  $i$ . Then the total traveling cost  $q_{\text{sum}}$  traveled by all vehicles, the total time window cost  $p_{\text{sum}}$  for start times of services, and the total amount  $a_{\text{sum}}$  of capacity excess are expressed

as follows:

$$p_{\text{sum}}(\mathbf{s}) = \sum_{i \in V \setminus \{0\}} p_i(s_i) + \sum_{k \in M} p_0(s_k^a),$$

$$q_{\text{sum}}(\boldsymbol{\sigma}, \mathbf{t}) = \sum_{k \in M} q_{0, \sigma_k(1)}(t_k^1) + \sum_{k \in M} \sum_{h=1}^{n_k} q_{\sigma_k(h), \sigma_k(h+1)}(t_{\sigma_k(h)}),$$

$$a_{\text{sum}}(\boldsymbol{\sigma}) = \sum_{k \in M} \max \left\{ \sum_{i \in V} a_i y_{ik}(\boldsymbol{\sigma}) - u_k, 0 \right\}.$$

Then the problem we consider in this paper is formulated as follows:

$$\text{minimize} \quad \text{cost}(\boldsymbol{\sigma}, \mathbf{s}, \mathbf{t}) = p_{\text{sum}}(\mathbf{s}) + q_{\text{sum}}(\boldsymbol{\sigma}, \mathbf{t}) + a_{\text{sum}}(\boldsymbol{\sigma}) \quad (2)$$

$$\text{subject to} \quad \sum_{k \in M} y_{ik}(\boldsymbol{\sigma}) = 1, \quad i \in V \setminus \{0\} \quad (3)$$

$$s_i \leq t_i, \quad i \in V \setminus \{0\} \quad (4)$$

$$t_k^1 + \lambda_{0, \sigma_k(1)}(t_k^1) \leq s_{\sigma_k(1)}, \quad k \in M \quad (5)$$

$$t_{\sigma_k(i)} + \lambda_{\sigma_k(i), \sigma_k(i+1)}(t_{\sigma_k(i)}) \leq s_{\sigma_k(i+1)}, \quad 1 \leq i \leq n_k - 1, \quad k \in M \quad (6)$$

$$t_{\sigma_k(n_k)} + \lambda_{\sigma_k(n_k), 0}(t_{\sigma_k(n_k)}) \leq s_k^a, \quad k \in M \quad (7)$$

$$y_{ik}(\boldsymbol{\sigma}) \in \{0, 1\}, \quad i \in V \setminus \{0\}, \quad k \in M. \quad (8)$$

Constraint (3) means that every customer  $i \in V \setminus \{0\}$  must be served exactly once by a vehicle. Constraint (4) requires that each vehicle must depart from customer  $i$  after the service and constraints (5)–(7) require that each vehicle cannot serve a customer before arriving at the customer. The time window and capacity constraints are treated as soft, and their violation is evaluated as the costs  $p_{\text{sum}}(\mathbf{s})$  and  $a_{\text{sum}}(\boldsymbol{\sigma})$  in the objective function. Note that, for any solution with a finite cost,  $t_k^1 \geq 0$  holds because of the assumptions, and hence  $\mathbf{s}, \mathbf{t} \geq 0$  hold.

Although we assume that each service takes no time, we can treat the case with positive constant service times by defining each traveling time and cost functions as  $\lambda_{ij}(t) = \tilde{b}_i + \tilde{\lambda}_{ij}(t + \tilde{b}_i)$  and  $q_{ij}(t) = \tilde{q}_{ij}(t + \tilde{b}_i)$  if the given traveling time and cost functions between customers  $i$  and  $j$  are  $\tilde{\lambda}_{ij}$  and  $\tilde{q}_{ij}$ , and the service time of customer  $i$  is  $\tilde{b}_i$ . In our formulation, a traveling cost function can be a constant function such as distance, which is a major objective function in traditional formulations, and hence our problem is a generalization of VRPSTW and the model of Ibaraki et al. [17].

This problem is separated into  $m$  scheduling problems for finding the optimal start times if vehicle routes  $\boldsymbol{\sigma}$  are fixed. Hence our algorithm searches  $\boldsymbol{\sigma}$  by local search and solves the corresponding  $m$  scheduling problems for each  $\boldsymbol{\sigma}$  generated during the search. In Section 3, we discuss this scheduling problem. How to search  $\sigma_k$  will be discussed in Section 4.

### 3. Optimal start time problem

In this section, we consider the problem of determining the optimal start times for a given route  $\sigma_k$  so that the total cost is minimized. Since the route is given, the objective function we have to consider is the sum of the time window costs and traveling costs. We call this subproblem the *optimal start time problem* and abbreviate it as OSTP in this paper.

For convenience, throughout this section, we assume that vehicle  $k$  visits customers  $1, 2, \dots, n_k$  in this order. Let customer 0 represent the departure from the depot (i.e.,  $t_0 = t_k^1$  and  $q_{0,1}(t_0) = q_{0,1}(t_k^1)$ ), and let customer  $n_k + 1$  represent the arrival at the depot (i.e.,  $s_{n_k+1} = s_k^a$  and  $p_{n_k+1}(s_{n_k+1}) = p_0(s_k^a)$ ).

Then, the OSTP is described as follows:

$$\text{minimize} \quad \sum_{h=1}^{n_k+1} p_h(s_h) + \sum_{h=0}^{n_k} q_{h, h+1}(t_h)$$

$$\text{subject to} \quad s_h \leq t_h, \quad 1 \leq h \leq n_k$$

$$t_h + \lambda_{h, h+1}(t_h) \leq s_{h+1}, \quad 0 \leq h \leq n_k.$$

Fig. 2. A function  $g$  and the linked list that represents  $g$ .

We can solve the OSTP by a dynamic programming algorithm in polynomial time as will be explained in Section 3.1.

### 3.1. Dynamic programming

We will show that the OSTP is solvable in polynomial time by using dynamic programming.

Let  $f_h(t)$  be the minimum sum of the time window costs for customers  $0, 1, \dots, h$  and the traveling costs between them under the condition that they are all served before time  $t$ .

We call  $f_h(t)$  a *forward minimum cost function*. Then it can be computed by the following recurrence formula of dynamic programming:

$$f_0(t) = \begin{cases} +\infty, & t < 0 \\ 0, & t \geq 0 \end{cases}$$

$$f_h(t) = \min_{s_h \leq t} \left\{ p_h(s_h) + \min_{t_{h-1}: t_{h-1} + \lambda_{h-1,h}(t_{h-1}) \leq s_h} \{f_{h-1}(t_{h-1}) + q_{h-1,h}(t_{h-1})\} \right\},$$

$$1 \leq h \leq n_k + 1, -\infty < t < +\infty. \quad (9)$$

The optimal cost of the OSTP for a route  $\sigma_k$  is given by  $\min_t f_{n_k+1}(t)$ .

### 3.2. Algorithm and time complexity

In this subsection, we consider the data structure and algorithm for computing forward minimum cost functions  $f_h$  in the recurrence formula (9). Since all functions of the input are piecewise linear, each  $f_h$  is also piecewise linear. We can therefore store all functions in linked lists; each cell stores the interval and the linear function of the corresponding piece, and the cells are linked according to the order of intervals. For example, Fig. 2 shows a piecewise linear function  $g$  and the corresponding linked list.

Let  $\delta(g)$  be the sum of the number of linear pieces and the number of discontinuous points of a piecewise linear function  $g$  (i.e., the number of pieces of the polygonal line of  $g$ ). For example, the function  $g$  in Fig. 2 has seven pieces and two discontinuous points, and hence  $\delta(g) = 9$ . Then it is straightforward to see that the summation  $g + g'$  of two piecewise linear functions  $g$  and  $g'$  can be computed in  $O(\delta(g) + \delta(g'))$  time and the resulting function satisfies  $\delta(g + g') \leq \delta(g) + \delta(g')$ . It is also easy to see that function  $\phi(t) = \min_{x \leq t} g(x)$  can be computed in  $O(\delta(g))$  time and the resulting function  $\phi$  satisfies  $\delta(\phi) \leq \delta(g)$ . When  $g$  is an increasing (resp., decreasing) piecewise linear function, i.e.,  $t < t' \Rightarrow g(t) < g(t')$  (resp.,  $t < t' \Rightarrow g(t) > g(t')$ ), we can compute the composite function  $g' \circ g$  (i.e.,  $g' \circ g(t) = g'(g(t))$ ) for a piecewise linear function  $g'$  in  $O(\delta(g) + \delta(g'))$  time since we can compute  $g'(g(t))$  by increasing  $g(t)$  gradually. In this case, the resulting function satisfies  $\delta(g' \circ g) \leq \delta(g) + \delta(g')$ . We can also compute the inverse of  $g$  in  $O(\delta(g))$  time, and the inverse  $g^{-1}$  satisfies  $\delta(g^{-1}) = \delta(g)$ .

Fig. 3. The relationship between the departure time  $t_{h-1}$  and the arriving time  $s = t_{h-1} + \lambda_{h-1,h}(t_{h-1})$ .

We define

$$\gamma_h(s) = \begin{cases} \min\{f_{h-1}(t) + q_{h-1,h}(t) \mid t + \lambda_{h-1,h}(t) = s\}, & \text{if } \{t \mid t + \lambda_{h-1,h}(t) = s\} \neq \emptyset, \\ \infty & \text{otherwise,} \end{cases}$$

and reformulate the above recurrence formula (9) as

$$f_h(t) = \min_{s_h \leq t} \left\{ p_h(s_h) + \min_{s \leq s_h} \gamma_h(s) \right\}. \quad (10)$$

To compute  $f_h$  by the recurrence formula (10), we must compute the function  $\gamma_h(s)$  first. Let us consider the plane whose horizontal axis corresponds to the start time  $t_{h-1}$  of traveling and the vertical axis corresponds to the arriving time  $s = t_{h-1} + \lambda_{h-1,h}(t_{h-1})$ . This is illustrated in Fig. 3. Then  $\gamma_h(s')$  for a fixed  $s = s'$  is the minimum value of  $f_{h-1}(t_{h-1}) + q_{h-1,h}(t_{h-1})$  among the points that satisfy

$$t_{h-1} + \lambda_{h-1,h}(t_{h-1}) = s', \quad (11)$$

if such a point exists. In order to compute  $\gamma_h(s)$ , we split the domain of  $t_{h-1}$  into increasing, constant and decreasing continuous parts and denote the closures of split intervals as  $D_1, D_2, \dots, D_L$  (see  $D_1, D_2, \dots, D_5$  in Fig. 3). Then, for each  $l = 1, 2, \dots, L$ , function  $t + \lambda_{ij}(t)$  on domain  $D_l$  admits the inverse or is a constant function. Let  $R_l$  be the range of  $t + \lambda_{ij}(t)$  on domain  $D_l$  (i.e.,  $R_l = \{t + \lambda_{ij}(t) \mid t \in D_l\}$ ). By condition (1) and the definition of  $D_l$ ,  $R_l \cap R_{l'}$  contains at most one point for any  $l \neq l'$ . Hence we can compute  $\gamma_h(s)$  partially for each domain  $D_l$  except for  $s \in \bigcup_{l \neq l'} R_l \cap R_{l'}$ . Then  $\gamma_h(s)$  is completed by merging them and taking the minimums for  $s \in \bigcup_{l=1}^L R_l \cap R_{l'}$ . Note that if  $s \notin \bigcup_{l=1}^L R_l$ , we define  $\gamma_h(s) = \infty$ . We have to arrange all  $R_l$ 's in the increasing order when we merge them, because the order of the appearance of  $R_l$  may be different from that of  $D_l$ . In Fig. 3, the order of the appearance of  $R_l$  is  $(R_1, R_2, R_3, R_5, R_4)$ . However, the order of  $R_l$ 's can be determined by  $\lambda_{ij}$  alone and needs to be computed only once before a search. This computation is negligible in comparison with the whole computation time. Hence we assume that the order of  $R_l$ 's for each  $\lambda_{ij}$  is given as a part of input.

We can now compute  $\gamma_h(s)$  by the following steps:

- (i) Compute  $\gamma_h|_{R_l}$  for each domain  $R_1, R_2, \dots, R_L$  by increasing  $t_{h-1}$  gradually and computing the corresponding  $\gamma_h(s)$ .
- (ii) Merge  $\gamma_h|_{R_l}$  for  $l = 1, 2, \dots, L$  and add linear pieces for the intervals with  $s \notin \bigcup_{l=1}^L R_l$ .

For computing each  $\gamma_h|_{R_l}$  for  $l = 1, 2, \dots, L$ , we need either to take the minimum (i.e.,  $\gamma_h(s) = \min\{f_{h-1}(t_{h-1}) + q_{h-1,h}(t_{h-1}) \mid t_{h-1} \in D_l\}$ ), or to calculate the composite function (i.e.,  $\gamma_h(s) = f_{h-1}(t_{h-1}) + q_{h-1,h}(t_{h-1})$  where  $t_{h-1} + \lambda_{h-1,h}(t_{h-1}) = s$  holds. We can compute  $t_{h-1}$  from  $s$  by taking the inverse of  $t_{h-1} + \lambda_{h-1,h}(t_{h-1})$ ). In both cases, the time complexity is linear to the number of the corresponding linear pieces of  $f_{h-1}$ ,  $q_{h-1,h}$  and  $\lambda_{h-1,h}$ .

During the whole computation of (i), we need to scan (the linked lists representing) the functions  $\lambda_{h-1,h}(t_{h-1})$  and  $f_{h-1}(t_{h-1}) + q_{h-1,h}(t_{h-1})$  only once from left to right. For completing  $\gamma_h$  by merging  $\gamma_h|_{R_l}$  for  $l = 1, 2, \dots, L$  in (ii), it is straightforward to see that the time complexity is  $O(L)$ . Hence the time complexity of computing function  $\gamma_h(s)$  is  $O(\delta(f_{h-1}) + \delta(q_{h-1,h}) + \delta(\lambda_{h-1,h}))$ , and  $\delta(\gamma_h) \leq \delta(f_{h-1}) + \delta(q_{h-1,h}) + \delta(\lambda_{h-1,h})$  holds.

Now we can compute  $f_h$  by the recurrence formula (10) in  $O(\delta(p_h) + \delta(\gamma_h))$  time, where the number of pieces of  $f_h$  is at most  $\delta(p_h) + \delta(\gamma_h)$ . Hence we can compute  $f_h$  from  $f_{h-1}$  in

$$O(\delta(f_{h-1}) + \delta(q_{h-1,h}) + \delta(\lambda_{h-1,h})) + O(\delta(p_h) + \delta(\gamma_h)) = O(\delta(f_{h-1}) + \delta(p_h) + \delta(q_{h-1,h}) + \delta(\lambda_{h-1,h}))$$

time and we have

$$\delta(f_h) \leq \delta(p_h) + \delta(\gamma_h) \leq \delta(f_{h-1}) + \delta(p_h) + \delta(q_{h-1,h}) + \delta(\lambda_{h-1,h}).$$

Hence we have

$$\delta(f_h) \leq \sum_{h'=1}^h \delta(p_{h'}) + \delta(q_{h'-1,h'}) + \delta(\lambda_{h'-1,h'}).$$

Using this, the time complexity of computing  $f_h$  from  $f_{h-1}$  is evaluated as

$$O\left(\sum_{h'=1}^h \delta(p_{h'}) + \delta(q_{h'-1,h'}) + \delta(\lambda_{h'-1,h'})\right).$$

In summary, given a route  $\sigma_k$ , we can compute the forward minimum cost function of a customer from that of the previous customer in  $O(\Delta(\sigma_k))$  time, where

$$\Delta(\sigma_k) = \sum_{h=1}^{n_k+1} \delta(p_{\sigma_k(h)}) + \delta(q_{\sigma_k(h-1),\sigma_k(h)}) + \delta(\lambda_{\sigma_k(h-1),\sigma_k(h)}).$$

We can then obtain the optimal cost of  $\sigma_k$  in  $O(n_k \Delta(\sigma_k))$  time by computing the forward minimum cost functions of  $n_k$  customers in  $\sigma_k$ , and taking the minimum of the forward minimum cost function of the depot. Note that  $\Delta(\sigma_k)$  is the same as the input size of the OSTP. If traveling cost and time functions are constant functions (i.e., if there is no time-dependency), this time complexity of the dynamic programming algorithm becomes the same as that of Ibaraki et al. [17].

### 3.3. Remarks for the case in which condition (1) does not hold

Even if condition (1) does not hold, we can compute  $\gamma_h(s)$  in a similar manner as in Section 3.2. Fig. 4 shows the same situation as Fig. 3 in which condition (1) does not hold. In order to compute  $\gamma_h(s)$ , we split the domain of  $t_{h-1}$  into the intervals  $D_1, D_2, \dots, D_L$  as before, compute the functions

$$\tilde{\gamma}_h^l(s) = f_{h-1}(t_{h-1}) + q_{h-1,h}(t_{h-1}),$$

where  $t_{h-1} + \lambda_{h-1,h}(t_{h-1}) = s$  and  $t_{h-1} \in D_l$ , for each  $R_l, l = 1, 2, \dots, L$ , and complete  $\gamma_h$  by taking the lower envelope of them.

In general, the complexity of the lower envelope of  $n$  segments is  $\theta(\alpha(n)n)$ , where  $\alpha$  denotes the inverse of Ackermann's function [18]. Using this fact, letting  $\Delta = \delta(f_{h-1}) + \delta(q_{h-1,h}) + \delta(\lambda_{h-1,h})$ , the complexity of  $\gamma_h$  is bounded by  $O(\alpha(\Delta)\Delta)$ . However, this upper bound is not small enough to prove that the complexity of  $f_h$  is of polynomial order. Hence our dynamic programming algorithm may require exponential time. Whether the algorithm runs in polynomial time or not, and whether the OSTP itself is NP-hard or not are both open.

### 3.4. Historical notes

The OSTP without time-dependency (i.e.,  $q_{h,h+1}(t)$  and  $\lambda_{h,h+1}(t)$  are constant functions) has been intensively studied in the literature especially when the time window cost functions  $p_h(s)$  are convex. Below is a brief summary of such results.

Fig. 4. An example of  $\lambda_{ij}$  which does not satisfy condition (1).

Special cases of convex time window cost functions were considered in the literature of VRPSTW and scheduling problems. In Taillard et al. [8], the time window cost for each customer is  $+\infty$  for earliness and linear for tardiness, and an  $O(1)$  time algorithm to approximately compute the optimal time window cost of a solution in the neighborhood was proposed. In Desrosiers et al. [2], the time window cost for each customer is linear in the time window and  $+\infty$  otherwise, and an  $O(n_k)$  time algorithm was presented. In Davis and Kanet [19], Koskosidis, Powell and Solomon [5], Tamaki, Komori and Abe [20], Tamaki, Sugimoto and Araki [21], the time window cost is linear for both earliness and tardiness, and an  $O(n_k^2)$  time algorithm was proposed in Davis and Kanet [19] and Tamaki, Sugimoto and Araki [21]. If the time window cost function for each customer is the absolute deviation from a specified time, this problem becomes the *isotonic median regression* problem, which has been extensively studied. To our knowledge, the best time complexity for this problem is  $O(n_k \log n_k)$  (Ahuja and Orlin [22], Garey, Tarjan and Wilfong [23], Hochbaum and Queyranne [24]). In Ibaraki et al. [25], the time window cost function for each customer is a piecewise linear convex function. They proposed an  $O(\Delta(\sigma_k) \log(\Delta(\sigma_k)))$  time algorithm to solve the problem from scratch, and an  $O(\log(\max_k \Delta(\sigma_k)))$  amortized time algorithm to compute the optimal cost of a solution in the neighborhood. In Dumas, Soumis and Desrosiers [26], general convex time window cost functions were considered for the VRPHTW, and they proposed an algorithm whose time complexity is of the order of  $n_k$  basic operations on the functions called uni-dimensional minimizations. Very fast algorithms for general convex functions are also known (Ahuja and Orlin [22], Hochbaum and Queyranne [24]).

For the case without time-dependency and with nonconvex time window costs, Ibaraki et al. [17] proposed an  $O(n_k \Delta(\sigma_k))$  time algorithm to solve the problem from scratch, and an  $O(\max_k \Delta(\sigma_k))$  amortized time algorithm to compute the optimal cost of a solution in the neighborhood. Sexton and Bodin [27] considered an OSTP for the pickup and delivery problem and proposed a linear-time algorithm. In their formulation of OSTP, a linear cost function on the duration between the pickup and delivery of each request is also considered, while the cost for each customer is linear for earliness and  $+\infty$  for tardiness, and time-dependency is not considered.

#### 4. Local search for finding visiting orders $\sigma$

In this section, we describe the framework of our local search (LS) for finding good visiting orders  $\sigma = (\sigma_1, \sigma_2, \dots, \sigma_m)$  that satisfy condition (3). It starts from an initial solution  $\sigma$  and repeats replacing  $\sigma$  with a better solution in its neighborhood  $N(\sigma)$  until no better solution is found in  $N(\sigma)$ . As  $N(\sigma)$  we use the standard neighborhoods called 2-opt\*, cross exchange and Or-opt with slight modifications (see Fig. 5). In this figure, squares represent the depot (which is duplicated at each end) and small circles represent customers in the routes. A thin line represents a route edge and a thick line represents a path (i.e., more than two customers may be included).

The 2-opt\* neighborhood was proposed in [6], which is a variant of the 2-opt neighborhood [28] for the traveling salesman problem. A 2-opt\* operation removes two edges from two different routes (one from each) to divide each

Fig. 5. Neighborhoods in our local search.

route into two parts and exchanges the second parts of the two routes. The cross exchange neighborhood was proposed in [8]. A cross exchange operation removes two paths from two routes (one from each) of different vehicles, whose lengths (i.e., the number of customers in the path) are at most  $L^{\text{cross}}$  (a parameter), and exchanges them. The cross exchange and 2-opt\* operations always change the assignment of customers to vehicles. We also use the intra-route neighborhood to improve individual routes, which is a variant of Or-opt neighborhood used for TSP [29,30]. An intra-route operation removes a path of length at most  $L_{\text{path}}^{\text{intra}}$  (a parameter) and inserts it into another position of the same route, where the position is limited within length  $L_{\text{ins}}^{\text{intra}}$  (a parameter) from the original position. Our LS searches the above intra-route neighborhood, 2-opt\* neighborhood and cross exchange neighborhood, in this order. Whenever a better solution is found, we immediately accept it (i.e., we adopt the first admissible move strategy), and resume the search from the intra-route neighborhood.

As only one execution of LS may not be sufficient to find a good solution, we use the *iterated local search* (ILS), which iterates LS many times from those initial solutions generated by perturbing good solutions obtained by them. We perturb a solution by applying one random cross exchange operation with no restriction on  $L^{\text{cross}}$  (i.e.,  $L^{\text{cross}} = n$ ). ILS is summarized as follows:

### ILS

**Step 1** Generate an initial solution  $\sigma^0$ . Let  $\sigma^{\text{seed}} := \sigma^0$  and  $\sigma^{\text{best}} := \sigma^0$ .

**Step 2** Improve  $\sigma^{\text{seed}}$  by LS and let  $\sigma$  be the improved solution.

**Step 3** If  $\sigma$  is better than  $\sigma^{\text{best}}$ , then replace  $\sigma^{\text{best}}$  with  $\sigma$ .

**Step 4** If some stopping criterion is satisfied, output  $\sigma^{\text{best}}$  and halt; otherwise generate a solution  $\sigma^{\text{seed}}$  by perturbing  $\sigma^{\text{best}}$  and return to Step 2.

## 5. Efficient implementation of local search

A solution  $\sigma$  is evaluated by  $(p+q)_{\text{sum}}^*(\sigma) + a_{\text{sum}}(\sigma)$ , where  $(p+q)_{\text{sum}}^*(\sigma)$  denotes the minimum time window and traveling time cost for computed  $\sigma$  by dynamic programming in Section 3. (Actually in our algorithm, we split each traveling cost function into the constant part and the time-dependent part, and compute them separately to improve the efficiency.) For this, it is important to see that dynamic programming computation of  $(p+q)_{\text{sum}}^*(\sigma)$  for the solutions in neighborhoods can be sped up by using information from the previous computation. A similar idea was originally proposed in Ibaraki et al. [17] for a simpler problem, in which the traveling times between customers were constants and no time-dependent traveling cost was considered. Below we will denote by  $\langle \sigma_k(h_1) \rightarrow \sigma_k(h_2) \rangle$  the path from the  $h_1$ th customer to the  $h_2$ th customer in route  $\sigma_k$ , and by  $\langle \sigma_k(h_1) \rightarrow \sigma_k(h_2) \rangle - \langle \sigma_{k'}(h_3) \rightarrow \sigma_{k'}(h_4) \rangle$  the path constructed by connecting two paths  $\langle \sigma_k(h_1) \rightarrow \sigma_k(h_2) \rangle$  and  $\langle \sigma_{k'}(h_3) \rightarrow \sigma_{k'}(h_4) \rangle$  from routes  $\sigma_k$  and  $\sigma_{k'}$ .

### 5.1. The basic idea

Consider the computation of the minimum cost (including the amount of capacity excess, the time window cost and the traveling time cost) for a given route  $\sigma_k = (\sigma_k(0), \sigma_k(1), \dots, \sigma_k(n_k + 1))$  when it is obtained by connecting its former part  $\langle 0 \rightarrow \sigma_k(h) \rangle$  and the latter part  $\langle \sigma_k(h+1) \rightarrow 0 \rangle$  for some  $h$  as illustrated in Fig. 6. The amount of capacity excess for route  $\sigma_k$  is computed in  $O(1)$  time, if both  $\sum_{i=1}^h a_{\sigma_k(i)}$  and  $\sum_{i=h+1}^{n_k} a_{\sigma_k(i)}$  are known. We therefore store  $\sum_{i=1}^h a_{\sigma_k(i)}$  and  $\sum_{i=h}^{n_k} a_{\sigma_k(i)}$  for each customer  $\sigma_k(h)$  and vehicle  $k$  whenever the current route is updated.

Fig. 6. The former and latter parts of a route  $\sigma_k$ .

Fig. 7. An example of a 2-opt\* operation.

Now we concentrate on the computation of  $(p + q)_{\text{sum}}^*(\sigma_k)$ , which is the minimum sum of time window and traveling time costs on route  $\sigma_k$ .

Let  $b_h^k(t)$  be the minimum sum of the time window costs for customers  $\sigma_k(h)$ ,  $\sigma_k(h+1)$ ,  $\dots$ ,  $\sigma_k(n_k+1)$  and the traveling costs between them provided that all of them are served after time  $t$ .

We call this a *backward minimum cost function*. Then,  $b_h^k(t)$  can be computed as follows, which is symmetric to the forward minimum cost computation discussed in Section 3:

$$b_{n_k+1}^k(t) = \min_{s \geq t} p_0(s),$$

$$b_h^k(t) = \min_{s \geq t} \left\{ p_{\sigma_k(h)}(s) + \min_{t' \geq s} \{ b_{h+1}^k(t' + \lambda_{\sigma_k(h), \sigma_k(h+1)}(t')) + q_{\sigma_k(h), \sigma_k(h+1)}(t') \} \right\}, \quad 1 \leq h \leq n_k. \quad (12)$$

Let  $f_h^k(t)$  be the forward minimum cost function at the  $h$ th customer in route  $\sigma_k$ . We can then obtain the optimal cost  $(p + q)_{\text{sum}}^*(\sigma_k)$  by

$$\min_t \left\{ b_h^k(t) + \min_{t' + \lambda_{\sigma_k(h-1), \sigma_k(h)}(t') \leq t} f_{h-1}^k(t') + q_{\sigma_k(h-1), \sigma_k(h)}(t') \right\} \quad (13)$$

for any  $h$  ( $1 \leq h \leq n_k + 1$ ). If  $f_{h-1}^k(t)$  and  $b_h^k(t)$  are already available for some  $h$ , this is possible in  $O(\Delta(\sigma_k))$  time (since the computation of (13) is similar to that of (9)). To achieve this, we store all functions  $f_h^k(t)$  and  $b_h^k(t)$  for each customer  $\sigma_k(h)$ , when these were computed in the process of LS.

In summary, we can compute the minimum cost of route  $\sigma_k$  in  $O(\Delta(\sigma_k))$  time, if we keep the data  $\sum_{i=1}^h a_{\sigma_k(i)}$ ,  $\sum_{i=h}^{n_k} a_{\sigma_k(i)}$ ,  $f_h^k(t)$  and  $b_h^k(t)$  for all  $h = 1, 2, \dots, n_k$  and  $k \in M$ .

In our algorithm, the number of pieces in forward and backward minimum cost functions is closely linked to the speed of our algorithm. Hence we consider its reduction. Since  $f_h^k(t)$  (resp.,  $b_h^k(t)$ ) is nonincreasing (resp., nondecreasing), there are usually many pieces with considerably large values in  $f_h^k(t)$  (resp., in  $b_h^k(t)$ ) for small (resp., large)  $t$ . Such pieces will not be used in evaluating improved solutions. We therefore shrink those pieces whose minimum values over their intervals are larger than the objective value of the current solution, into one piece.

## 5.2. How to apply the basic idea to the solutions in neighborhoods

We now explain how to apply the above idea to evaluate solutions in the neighborhoods efficiently. We only discuss the sum of time window and traveling costs, since the amount of capacity excess can be similarly treated. Recall that we can compute the forward minimum cost function (resp., the backward minimum cost function) of a customer from that of the previous customer (resp., the next customer) in  $O(\Delta(\sigma_k))$  time, and that we can evaluate the route cost by connecting the forward and backward minimum cost functions in  $O(\Delta(\sigma_k))$  time.

In Fig. 7, an example of a 2-opt\* operation on routes  $\sigma_k$  and  $\sigma_{k'}$  is shown. We denote by  $\sigma_k^{\text{new}}$  and  $\sigma_{k'}^{\text{new}}$  the resulting two routes (i.e.,  $\sigma_k^{\text{new}} = \langle 0 \rightarrow \sigma_k(h_k) \rangle - \langle \sigma_{k'}(h_{k'} + 1) \rightarrow 0 \rangle$  and  $\sigma_{k'}^{\text{new}} = \langle 0 \rightarrow \sigma_{k'}(h_{k'}) \rangle - \langle \sigma_k(h_k + 1) \rightarrow 0 \rangle$ ). Then,

Fig. 8. An example of the search order in the cross exchange neighborhood.

the sum of time window and traveling time costs for  $\sigma_k^{\text{new}}$  can be computed by

$$\min_t \left\{ b_{h_{k'}+1}^{k'}(t) + \min_{t' + \lambda_{\sigma_k(h_k), \sigma_{k'}(h_{k'}+1)}(t') \leq t} f_{h_k}^k(t') + q_{\sigma_k(h_k), \sigma_{k'}(h_{k'}+1)}(t') \right\}$$

in  $O(\Delta(\sigma_k^{\text{new}}))$  time. Similarly the cost for  $\sigma_{k'}^{\text{new}}$  can be computed in  $O(\Delta(\sigma_{k'}^{\text{new}}))$  time. Hence, when a 2-opt\* operation is applied to routes  $\sigma_k$  and  $\sigma_{k'}$ , we can evaluate the cost of the resulting solution in  $O(\Delta(\sigma_k^{\text{new}}) + \Delta(\sigma_{k'}^{\text{new}}))$  time.

To evaluate solutions in the cross exchange neighborhood efficiently, we need to search the solutions in the neighborhood in a specific order. To apply cross exchange operations on routes  $\sigma_k$  and  $\sigma_{k'}$ , we start from a solution obtainable by exchanging one customer from each route, and then extend lengths of the paths to be exchanged one by one. Fig. 8 explains the situation. We denote by  $\sigma_k^{\text{tmp}}$  and  $\sigma_{k'}^{\text{tmp}}$  the routes obtained by applying a cross exchange operation on the current routes  $\sigma_k$  and  $\sigma_{k'}$  (see Fig. 8(a)) and by  $\sigma_k^{\text{new}}$  and  $\sigma_{k'}^{\text{new}}$  the routes generated next (see Fig. 8(b)). In Fig. 8(a), backward minimum cost functions  $b_{h_k}^k$ ,  $b_{h_{k'}}^{k'}$  and  $b_{h_{k'}+1}^{k'}$  of the current routes  $\sigma_k$  and  $\sigma_{k'}$  are available, and we have already computed the forward minimum cost functions  $\tilde{f}_1^k, \tilde{f}_2^k, \dots, \tilde{f}_l^k$  (resp.,  $\tilde{f}_1^{k'}, \tilde{f}_2^{k'}, \dots, \tilde{f}_{l'}^{k'}$ ) on the partial paths in  $\sigma_k^{\text{tmp}}$  (resp.,  $\sigma_{k'}^{\text{tmp}}$ ) in the process of computing  $(p+q)_{\text{sum}}^*(\sigma_k^{\text{tmp}})$  (resp.,  $(p+q)_{\text{sum}}^*(\sigma_{k'}^{\text{tmp}})$ ). We then compute  $\tilde{f}_{l+1}^k$  from  $\tilde{f}_l^k$  by recursion of the dynamic programming in  $O(\Delta(\sigma_k^{\text{new}}))$  time, and evaluate  $(p+q)_{\text{sum}}^*(\sigma_k^{\text{new}}) + (p+q)_{\text{sum}}^*(\sigma_{k'}^{\text{new}})$  in  $O(\Delta(\sigma_k^{\text{new}}) + \Delta(\sigma_{k'}^{\text{new}}))$  time (Fig. 8(b)). Thus, we can compute the change in the cost after a cross exchange operation in  $O(\Delta(\sigma_k^{\text{new}}) + \Delta(\sigma_{k'}^{\text{new}}))$  time.

Similarly, the change in the cost for an intra-route operation of route  $\sigma_k$  can be computed in  $O(\Delta(\sigma_k^{\text{new}}))$  time, by searching solutions in a specific order, where  $\sigma_k^{\text{new}}$  denotes the route generated by an intra-route operation. Actually, this case is slightly more complicated than the case of cross exchange neighborhood, but the search order described in Ibaraki et al. [17] also works for our problem.

### 5.3. Restriction of neighborhoods

In searching neighborhoods, we find that there are many solutions which have no prospects of improvements. In order to avoid evaluating such solutions, we propose a rule to restrict the search.

For a constant  $U$ , let

$$F_h^k(U) = \begin{cases} \min\{t \mid f_h^k(t) \leq U\}, & \text{if } \min_t f_h^k(t) \leq U \\ +\infty, & \text{otherwise.} \end{cases}$$

This  $F_h^k(U)$  gives the earliest departure time of vehicle  $k$  from customer  $\sigma_k(h)$  in order to keep the sum of the time window cost of customers  $\sigma_k(1), \sigma_k(2), \dots, \sigma_k(h)$  and the traveling cost between them below  $U$ . In other words

$$t \geq F_h^k(U) \iff f_h^k(t) \leq U$$

holds. As mentioned in Section 3.2, we store  $f_h^k(t)$  in a linked list; however, we can also store  $f_h^k(t)$  in an array without sacrificing the time complexity. Using this array data structure, we can compute  $F_h^k(U)$  for a given  $U$  in  $O(\log(\delta(f_h^k)))$  time because  $f_h^k$  is a nonincreasing function. (In our program, however, we did not implement the array structure, and used  $O(\delta(f_h^k))$  time to compute  $F_h^k(U)$ , because this does not seem to be a bottleneck of computation.)

Similarly let

$$B_h^k(U) = \begin{cases} \max\{t \mid b_h^k(t) \leq U\}, & \text{if } \min_t b_h^k(t) \leq U \\ -\infty, & \text{otherwise.} \end{cases}$$

$B_h^k(U)$  is the latest arrival time of vehicle  $k$  at customer  $\sigma_k(h)$  in order to keep the time window cost of customers  $\sigma_k(h), \sigma_k(h+1), \dots, \sigma_k(n_k+1)$  and the traveling cost between them below  $U$ . Note also that

$$t \leq B_h^k(U) \iff b_h^k(t) \leq U$$

holds, because  $b_h^k$  is a nondecreasing function, and we can compute  $B_h^k(U)$  in  $O(\log(\delta(b_h^k)))$  time. Then, if

$$F_{h-1}^k(U) + \lambda_{k,h}^{\min} > B_h^k(U)$$

holds for  $\lambda_{k,h}^{\min} = \min_t \lambda_{\sigma_k(h-1), \sigma_k(h)}(t)$ , the cost of route  $\sigma_k$  must be larger than  $U$ . This fact is utilized to restrict the search in the 2-opt\* and cross exchange neighborhoods, whose details are explained in Sections 5.3.1 and 5.3.2.

Furthermore, for any nonnegative nonincreasing function  $f$  and any nonnegative nondecreasing function  $b$ , we can obtain lower and upper bounds of  $\min_t \{f(t) + b(t)\}$  by the following observation. Let a point  $\hat{t}$  satisfy that  $t \geq \hat{t} \Rightarrow b(t) \geq f(\hat{t})$  and  $t \leq \hat{t} \Rightarrow f(t) \geq b(\hat{t})$ , and we call this the *switch point* of  $f$  and  $b$ . Then the switch point  $\hat{t}$  satisfies

$$\max\{f(\hat{t}), b(\hat{t})\} \leq \min_t \{f(t) + b(t)\} \leq f(\hat{t}) + b(\hat{t}) \leq 2 \max\{f(\hat{t}), b(\hat{t})\}.$$

If there is no switch point, either  $f(t) > b(t)$  or  $f(t) < b(t)$  holds for all  $t$ . In this case if  $f(t) > b(t)$  holds for all  $t$ , then

$$f(\tilde{t}) \leq \min_t \{f(t) + b(t)\} \leq f(\tilde{t}) + b(\tilde{t}) \leq 2f(\tilde{t})$$

holds, where  $\tilde{t} = \arg \min_t f(t)$ . When  $f$  and  $b$  are continuous, the switch point is the intersecting point of  $f$  and  $b$ .<sup>1</sup> From this property, for any  $h \in \{1, 2, \dots, n_k + 1\}$ , if  $\lambda_{\sigma_k(h-1), \sigma_k(h)}(t)$  is a constant function and  $q_{\sigma_k(h-1), \sigma_k(h)} = 0$ , we can obtain a lower bound on the OSTP from the switch point of  $f_{h-1}^k(t)$  and  $b_h^k(t + \lambda_{\sigma_k(h-1), \sigma_k(h)}(t))$ , and the schedule induced by the switch point becomes a 2-approximate schedule for  $\sigma_k$  (i.e., the cost of the schedule is at most  $2(p+q)_{\text{sum}}^*(\sigma_k)$ ), where cost can be computed in  $O(\log(\delta(f_{h-1}^k)) + \log(\delta(b_h^k))) = O(\log(\Delta(\sigma_k)))$  time. Even if  $\lambda_{\sigma_k(h-1), \sigma_k(h)}$  and  $q_{\sigma_k(h-1), \sigma_k(h)}$  are time-dependent, the switch point of  $f_{h-1}^k(t)$  and  $b_h^k(t + \lambda_{k,h}^{\min})$  gives a lower bound on the optimal cost. Hence we can skip solving the OSTP optimally in the search for neighborhoods if its lower bound indicates that it cannot improve the current  $\sigma$ .

### 5.3.1. 2-opt\* neighborhood

Consider the evaluation of a solution in the 2-opt\* neighborhood obtained by reconnecting two routes  $\sigma_k$  and  $\sigma_{k'}$  (see Fig. 7). We set a threshold  $U$ , and avoid evaluating the routes if we can conclude that  $(p+q)_{\text{sum}}^*(\sigma_k^{\text{new}}) + (p+q)_{\text{sum}}^*(\sigma_{k'}^{\text{new}}) > U$ . As our purpose is to obtain a better solution than the current one, we can set  $U$  as the total cost of the current routes  $\sigma_k$  and  $\sigma_{k'}$ . Our first idea is based on the following fact: The solution obtained by connecting  $\sigma_k(h_k)$  and  $\sigma_{k'}(h_{k'}+1)$  will have a cost larger than  $U$  if  $F_{h_k}^k(U) > B_{h_{k'}+1}^{k'}(U)$  holds. Let

$$P_{\text{valid}}^{kk'}(U) = \left\{ (\sigma_k(h_k), \sigma_{k'}(h_{k'})) \mid F_{h_k}^k(U) \leq B_{h_{k'}+1}^{k'}(U) \text{ and } F_{h_{k'}}^{k'}(U) \leq B_{h_k+1}^k(U) \right\}.$$

Then we can compute  $P_{\text{valid}}^{kk'}(U)$  in  $O(n_k + n_{k'} + |P_{\text{valid}}^{kk'}(U)|)$  time if  $F_{h_k}^k(U)$ ,  $B_{h_k}^k(U)$ ,  $F_{h_{k'}}^{k'}(U)$  and  $B_{h_{k'}}^{k'}(U)$  are available for all  $h_k$  and  $h_{k'}$ . It takes  $O(n_k \Delta(\sigma_k) + n_{k'} \Delta(\sigma_{k'}))$  time for the preprocessing of  $(O(n_k \log(\Delta(\sigma_k)) + n_{k'} \log(\Delta(\sigma_{k'}))))$  time if we use the array structure). Such preprocessing is necessary only when the current solution

<sup>1</sup> In our implementation, we just took an intersecting point instead of a switch point, because all functions of the tested instances are continuous.

is changed (i.e., when an improved solution is found or a perturbation is applied), and is usually dominated by the evaluation time of solutions.

Let

$$P_{\text{valid}}(U) = \bigcup_{k \neq k'} P_{\text{valid}}^{kk'}(U).$$

Then we can compute  $P_{\text{valid}}(U)$  in  $O(nm + |P_{\text{valid}}(U)|)$  time. Any solution cannot be better than the current solution unless it is induced from  $P_{\text{valid}}(U)$ .

Hence we restrict the 2-opt\* neighborhood only to the solutions induced from  $P_{\text{valid}}(U)$ . Although the size of the 2-opt\* neighborhood is reduced from  $O(n^2)$  to  $O(|P_{\text{valid}}(U)|)$  by this modification, we miss no better solution in the 2-opt\* neighborhood.

### 5.3.2. Cross exchange neighborhood

Consider the search in the cross exchange neighborhood. The size of the cross exchange neighborhood is  $O(n^2(L^{\text{cross}})^2)$ , and is largest in the standard neighborhoods used in this paper. Here we consider a restriction of the cross exchange neighborhood. In order to keep the change in the time window costs and traveling time costs small, it seems preferable to keep the arriving times at customers in the generated solution close to those of the current solution. Based on this intuition, we restrict the paths to be exchanged with those which satisfy  $(\sigma_k(h_1^k), \sigma_{k'}(h_1^{k'})) \in P_{\text{valid}}^{k,k'}(U)$ , where  $\sigma_k(h_1^k)$  and  $\sigma_{k'}(h_1^{k'})$  are the first customers of the paths. Note that, different from the case of 2-opt\* neighborhood, this restriction has a possibility of missing a better solution in the cross exchange neighborhood.

## 6. Computational results

We conducted computational experiments to evaluate the proposed algorithm ILS. The algorithm was coded in C language and run on a handmade PC (Intel Pentium 4, 2.8 GHz, 1 GB memory). We used  $L^{\text{cross}} = 3$ ,  $L_{\text{path}}^{\text{intra}} = 3$  and  $L_{\text{ins}}^{\text{intra}} = 15$  in the experiments.

### 6.1. Effect of the restriction of the neighborhoods

We first consider the effect of the restriction of the neighborhoods discussed in Section 5.3. We run our local search algorithm with the 2-opt\* neighborhood only, from a random solution and a locally optimum solution, both with and without restriction. We use the same random solution and the same locally optimal solution for the initial solutions of the runs with and without restriction. In a similar manner, we also test our local search algorithm with the cross exchange neighborhood only. For these tests, we used the instance r201 in Solomon's benchmark list, whose details will be described in Section 6.2.

Fig. 9 shows the results with the 2-opt\* neighborhood without (left) and with (right) restriction, respectively, whose vertical axis gives the total cost of every two routes constructed as neighborhood solutions, while the horizontal axis shows the cost before the neighborhood operation is applied (i.e., the current solution). Namely, each point in the figure corresponds to the two route cost of a neighborhood solution. Similarly, Fig. 10 shows the results with the cross exchange neighborhood.

From these figures, we observe that the proposed restriction succeeds in avoiding the evaluations of solutions whose costs are much larger than that of the current solutions. We can also observe that the restriction becomes more effective when the cost of the current solution is small.

Then Table 1 shows the number of cost evaluations needed to obtain a locally optimal solution, with and without restriction of neighborhood. Column “random” (resp., “locally optimal”) shows the number of evaluations during the local search when the initial solution is a random (resp., locally optimal) solution. Note that, in the case of the locally optimal initial solution, no improvement is achieved as a result of local search. The two rows correspond to the cases with and without restriction, respectively, where the values in parenthesis are the objective values of the obtained locally optimal solutions.

From Table 1, we can confirm the effectiveness of the restriction. In the neighborhood of a random solution we can reduce the number of evaluations to almost half, and in the neighborhood of a locally optimal solution, we can reduce it to only a few percent. In our restriction of 2-opt\* neighborhood, the solution quality is basically the same since the restriction is guaranteed not to miss any improved neighborhood solution. However, the objective values are different

Fig. 9. The distribution of two route cost in the 2-opt\* neighborhood without (left) and with (right) restriction.

Fig. 10. The distribution of two route cost in the cross exchange neighborhood without (left) and with (right) restriction.

Table 1

Number of evaluations with and without restriction of neighborhood

Neighborhood	2-opt*		Cross exchange	
Initial solution	Random	Locally optimal	Random	Locally optimal
Without restriction	227 746 (11016.59)	4035 (1253.23)	333 321 (1607.82)	24 875 (1253.23)
With restriction	146 440 (17906.10)	164 (1253.23)	139 771 (1518.22)	111 (1253.23)

in the table, because we use random numbers when we determine the search order in neighborhood. Although we may miss improved solutions in the case of the cross exchange neighborhood with restriction, the output solution happens to be slightly better than that obtained without restriction in this particular case. Since each run of local search resumes from a solution generated by applying a small perturbation on a good locally optimal solution in our ILS algorithm, the effect of the restriction is expected to be significant.

## 6.2. The vehicle routing problem with hard time windows

We used Solomon's benchmark instances [31] and Gehring and Homberger's benchmark instances [32], which have been widely used in the literature. We first explain Solomon's instances. The number of customers in each instance is 100, and their locations are distributed in the square  $[0, 100]^2$  in the plane. The distances between customers are measured by Euclidean distances (in double precision), and the traveling times are the same as the corresponding distances. Each customer  $i$  (including the depot) has one time window  $[r_i, d_i]$ , an amount of requirement  $a_i$  and a service time  $b_i$ . All vehicles have an identical capacity  $u$ . Both time window and capacity constraints are considered to be hard. For these instances, the number of vehicles  $m$  is also a decision variable, and the objective is to find a solution with the minimum vehicle number and the total traveling distance in the lexicographical order. These benchmark instances consist of six different sets of problem instances called R1, R2, RC1, RC2, C1 and C2, respectively. Locations of customers are uniformly and randomly distributed in type R and are clustered into groups in type C, and these two types are mixed in type RC. Furthermore, for the instances of type 1, the time window is narrow at the depot, and hence only a small number of customers can be served by one vehicle. On the contrary, for the instances of type 2, the time window at the depot is wide, and many customers can be served by one vehicle. Recently, 300 instances with larger number of customers are added by Gehring and Homberger [32], which are divided into five groups by the number of customers, 200, 400, 600, 800 and 1000, where each group has 10 instances for each of six types (i.e., R1, R2, RC1, RC2, C1 and C2).

In order to handle the above instances by our algorithm, we define time window cost function  $p_i$ , traveling cost functions  $q_{ij}$  and traveling time functions  $\lambda_{ij}$  as follows:

$$p_i(t) = \begin{cases} \alpha(r_i - t), & t < r_i \\ 0, & r_i \leq t \leq d_i \\ \alpha(t - d_i), & d_i < t, \end{cases}$$

$$q_{ij}(t) = c_{ij},$$

$$\lambda_{ij}(t) = b_i + c_{ij},$$

where  $\alpha$  is a positive parameter and  $c_{ij}$  is the distance (as well as the traveling time) between customers  $i$  and  $j$ . Note that, in this formulation, the time window constraint is considered as soft, and can be violated if it is advantageous from the view point of minimizing the cost function. We set the number of vehicles in each instance to what is used in [25].

We first conduct preliminary experiments to determine parameter value  $\alpha$  for each instance. We run the algorithm with some values of  $\alpha$  from  $\{1, 5, 10, 50, 100, 500, \dots\}$  in the manner of binary search, where the time limit for each  $\alpha$  was within 10% of the time limit reported in the tables in this section. Then we use the best  $\alpha$  among them and the adjacent values in both directions (e.g., if the best results were obtained with  $\alpha = 50$ , we use 10, 50 and 100 for  $\alpha$ ), run the algorithm by using the three values of  $\alpha$  with 100% of the time limit, and report the best result below. If we cannot find a feasible solution, which satisfies the hard time window and capacity constraints, even with  $\alpha = 1000\,000$ , we increase the number of vehicles by one. Actually we could find a feasible solution for every instance except for six instances, and, for the six instances, we could find feasible solutions with one more vehicle.

We then compare the solutions obtained by our experiments with those obtained by existing methods. For Solomon's instances, the time limit of our algorithm is 1000 s for each instance. The results are shown in Table 2. In this table, "CNV" represents the cumulative number of vehicles, and "CTD" represents the cumulative total distance, which are usually used in the literature to compare the results on Solomon's instances. The upper (resp., lower) part of each cell in the table shows the mean number of vehicles (resp., the mean total distance) with respect to all instances for the type. Columns "IKMU", "HG99", "GH02", "BBB", "B", "BVH", "HG03", "IINSUY" and "ILS" are the results of Ibaraki et al. [17], Homberger and Gehring [33], Gehring and Homberger [34], Berger et al. [35], Bräysy [36], Bent and Van Hentenryck [37], Homberger and Gehring [32], Ibaraki et al. [25] and our ILS algorithm, respectively. The bottom rows describe the computer, the average CPU time and the number of independent runs for each method reported by the author, where "P" and "SU" mean Pentium and SUN Ultra, respectively. The row "Computer" contains the clock frequency of the computer (e.g., "P 200" means a computer whose CPU is Pentium 200MHz). Computation time of "HG03" is not clearly stated in [32]. To make a fair comparison of the performance of various algorithms, we estimate the total computation time for each experiment by using the SPEC data presented in the web page of SPEC (<http://www.specbench.org/>). The row "Estimated time" represents this estimated time. An asterisk "\*" in rows of the mean number of vehicles indicates that the value is the best among all the algorithms in the

table and there is no tie. When there are ties for the number of vehicles, we give an asterisk “\*” on the corresponding distance value that is the smallest among those ties. In the row CNV, all results with the smallest value get “\*”.

The results for Gehring and Homberger’s instances are given in Tables 3–7. The time limit of our algorithm for 200, 400, 600, 800 and 1000-customer instances are 2000, 4000, 6000, 8000 and 10 000 s, respectively. Columns “GH99”, “GH01”, “BVH”, “LL”, “LC”, “BHD” “MB” and “IINSUY” are the results by Gehring and Homberger [38], Gehring and Homberger [34], Bent and Van Hentenryck [37], Li and Lim [39], Le Bouthillier and Crainic [40], Bräysy et al. [41], Mester and Bräysy [42] and Ibaraki et al. [25] respectively. “AMD” in the row “Computer” means Advanced Micro Devices and “n/a” in the row “CPU(min)” and “Runs” means that the data is not available.

In Table 2, our ILS obtained CNV 405 and the smallest CTD among all the tested algorithms. According to a recent survey by Bräysy and Gendreau [10], not many algorithms achieved CNV 407 or less, and only those algorithms cited in Table 2 achieved CNV 405. In Tables 3–7, we could also obtain the smallest CNV among the tested algorithms. The computation time of our ILS is reasonable compared to others especially for larger instances. These results indicate that our ILS is highly efficient to solve the vehicle routing problem with time windows, in spite of its high generality. More details of the computational results for those instances to which we found better solutions than the best known solutions are presented in Tables 8–12. Column “Inst” shows the names of the instances, column “distance” shows the total traveling distances and column “bknown” shows the best known solutions for these instances, where the data was taken as of June 2, 2004 from <http://www.sintef.no/static/am/opti/projects/top/vrp/benchmarks.html>. An asterisk “\*” in a row means that the value is better than that of “bknown”. The details of the computational results for all instances are contained in Hashimoto [43]. Here it should be noted that we had to determine parameter  $\alpha$  by preliminary experiments to achieve the above results, since the performance is crucially dependent on the value. Though the time spent for such tuning was not so large, it is one of the important directions of our future research to develop a mechanism to find a good value of  $\alpha$  automatically.

### 6.3. Time-dependent VRPSTW

Our algorithm ILS is designed for a more general problem than the standard VRPSTW, i.e., time-dependent VRPSTW. In order to test the performance of ILS, we generated 56 instances of time-dependent VRPSTW by modifying Solomon’s instances, as suggested by Ichoua et al. [15].

In these instances, all traveling between customers are categorized into three types, and the scheduling horizon (i.e., the time window at the depot) consists of morning, daytime and evening. The travel speed of a vehicle depends on the category and the period of scheduling horizon, which is further classified into three scenarios as shown in

**Table 13.** Time-dependency is small, medium and large in scenarios 1, 2 and 3, respectively. Note that the average speed in each scenario is approximately 1, and the difficulty of time window constraints is similar to Solomon's instances. We define the time window cost function as

$$p_i(t) = \begin{cases} r_i - t, & t < r_i \\ 0, & r_i \leq t \leq d_i \\ t - d_i, & d_i < t, \end{cases}$$

and we construct each traveling time function  $\lambda_{ij}(t)$  from the distance and travel speed in Table 13. We then define  $q_{ij}(t) = \lambda_{ij}(t)$ .

Table 14 shows the computational results of our algorithm ILS for these instances. Column “time-dependent” represents the results of our algorithm devised for the time-dependent instances. Column “const” represents the results obtained by the following method, which was tested for comparison purposes: We solved the instances with our algorithm after replacing the time-dependent traveling time with the fixed constant determined by taking the average of the traveling time in the whole periods. Note that, in the case of “const”, even though the constant traveling times were used during the search, the final cost outputs by this method were evaluated exactly under the time-dependent environment, and the table shows the results under the exact evaluation. Each row gives the instance type, and the

In Table 14, we can observe that both  $p_{\text{sum}}$  and  $q_{\text{sum}}$  in column “time-dependent” are smaller than those in column “const”. The difference becomes larger as the instances become more time-dependent (i.e., from scenarios 1 to 3). This indicates the usefulness of our algorithm that can accept time-dependency.

## 7. Conclusion

We generalized the standard vehicle routing problem with time windows by allowing both traveling times and traveling costs to be time-dependent functions, and proposed an iterated local search algorithm. Our generalization can treat time-dependent traveling times and costs such as rush-hour traffic jam, and includes various interesting problems such as parallel machine scheduling problems as its special cases.

In our local search procedure, for each vehicle route generated during the search, we must compute an optimal schedule for the route. We showed that this subproblem can be efficiently solved by dynamic programming. We further proposed a filtering method that restricts the size of neighborhoods, based on the fact that there are many solutions having no prospect of improvement. We developed an iterated local search algorithm incorporating all the above ingredients. The computational results on representative benchmark instances indicate that the proposed algorithm is
